Abstract

Extra pulmonary tuberculosis occurs in 20% of patients with tuberculosis. Tuberculosis pericarditis is seen in 1-8% of these patients. Tuberculosis has been reported to be the cause of acute pericarditis in 60-80% of the patients in the developing world. We reported a case of 19 years old male who presented with right chest pain, cough, breathlessness, night sweat, fever, fatigue, and weight loss. From the physical examination, jugular venous pressure was high and on auscultation, the heart sounds were muffled and associated with a pericardial rub. The chest x-ray revealed enlargement of cardiac silhouette. Transthoracic echocardiography showed pericardial effusion, and mantoux tuberculin skin test were positive. Since the pericardiocentesis is not feasible in our hospital, the tygerberg tuberculous pericarditis score was applied. Furthermore, patients were given anti-TB treatment, and showed a good response to treatment.

Key words: extra pulmonary tuberculosis, tuberculous pericarditis, tygerberg score

Penggunaan Skor Tygerberg untuk Diagnosis dan Tatalaksana Perikarditis Tuberkulosis

Abstrak

Kata kunci: tuberkulosis ekstra pulmoner, perikarditis tuberkulosis, skor tygerberg
Introduction

Tuberculosis (TB) can involve any organ system in the human body. Pulmonary TB is the most common presentation, but extra-pulmonary tuberculosis (EPTB) is also an important clinical problem. It has been observed that EPTB constituted about 15-20% of all cases of TB. Tuberculosis pericarditis has been estimated to occur in 1-8% patients with pulmonary tuberculosis. Tuberculosis has been reported to be the cause of acute pericarditis in 4% of patients in the developed world and 60-80% of the patients in the developing countries.1-5 Pericardial involvement usually develops by retrograde lymphatic spreading of the organism, *Mycobacterium tuberculosis*, from peritracheal, peribronchial, or mediastinal lymph nodes or by hematogenous spread from primary tuberculous infection. The pericardium is infrequently involved by breakdown and contiguous spread from a tuberculous lesion in the lung or by hematogenous dissemination from distant secondary skeletal or genitourinary infection. The immune response to the viable acid-fast bacilli penetrating the pericardium is responsible for the morbidity associated with tuberculous pericarditis. Protein antigens of the bacillus induce delayed hypersensitivity responses, stimulating lymphocytes to release lymphokines that activate macrophages and influence granuloma formation. The cytokine profile suggests that tuberculous pericardial effusions arise as a result of a hypersensitivity reaction orchestrated by the Th-1 lymphocytes.

Tuberculous pericarditis presents clinically in three forms, namely, pericardial effusion, constrictive pericarditis, and a combination of effusion and constriction.6 Tuberculous pericardial effusion usually develops insidiously, presenting with nonspecific systemic symptoms such as fever, night sweats, fatigue, and weight loss. Chest pain, cough, and breathlessness are common.

Right upper abdominal aching due to liver congestion is also common. The patients may manifest pericardial rub, vague chest pain, cardiomegaly on a chest radiograph, and echocardiography reveal pericardial effusion. Cardiac tamponade and constrictive pericarditis are major lethal complications of TB pericarditis. According to Reuter et al.,7 definite tuberculous pericarditis was diagnosed by one or more of the following criteria: (i) “demonstration and isolation of *M. tuberculosis* from the drained pericardial effusion or pericardial biopsy sample; (ii) demonstration of granulomatous inflammation on histological examination of the pericardial biopsy sample; and/or (iii) isolation of *M. tuberculosis* from sputum or non-pericardial exudates in the presence of clinical and/or radiological evidence of TB, associated with a positive response to anti-tuberculous therapy.”

Tuberculin skin test (mantoux test) has little value of diagnostic, especially in highly endemic area such as Indonesia. It is due to the mass Bacille Calmette Guerin (BCG) immunization, but large induration more than 10 mm in diameter is suspicious for TB. Tygerberg TB pericarditis diagnosis score is applicable when pericardiocentesis is not feasible. For proper treatment, accurate diagnosis of tuberculous pericarditis is very important. Without specific treatment, the mean survival rate is 3.7 months, with a mortality rate approaching 85% at six months. Effective treatment requires a rapid and accurate diagnosis, but this is often difficult. It is important to identify which clinical and basic laboratory features should be used.

Case Presentation

A case of a 19 years old male presented with right chest pain, cough, breathlessness, night sweat, fever, fatigue, and weight loss. On physical examination, jugular venous
pressure was high and on auscultation, the heart sounds were muffled and associated with a pericardial rub. There was no peripheral edema, cyanosis, pallor, icterus or hepatosplenomegaly. Laboratory investigation revealed anemia, increased erythrocyte sedimentation rate (ESR) 85 mm, haemoglobin (Hb) was 10.7 gr/dl, white blood cells (WBC) was 9000/mm³, platelet count was 615 000/mm³. The result of WBC differential was: -1/10/58/26/5 (%), serum globulin 4.6 mg/dL, albumin 3.32 mg/dL and anti-streptolysin O (ASTO) titer was negative. The chest x-ray revealed enlargement of cardiac silhouette. Transthoracic echocardiography showed pericardial effusion, and mantoux tuberculin skin test were highly positive. Electrocardiography showed low voltage complexes with sinus tachycardia. A working diagnosis of tuberculous pericarditis was diagnosed without active pulmonary tuberculosis finding. Definitive diagnosis of tuberculosis etiology was challenging because we did not do the pericardiocentesis due to limitation of tools and diagnostic approach. Because pericardiocentesis is not feasible in our hospital, we applied tygerberg TB pericarditis diagnostic score and showed total score ≥ 6, which indicated tuberculosis pericarditis. The patient was given empiric antituberculosis chemotherapy with isoniazid (5 mg/kg per day), rifampicine (10 mg/kg per day), ethambutol (20 mg/kg per day), pyrazinamide (20 mg/kg per day), and in addition, the patients received corticosteroid at initial dose of prednisone 1 mg/kg per day, then tapped down. The patient was responding well to the treatment, with no recurrence of symptoms or any signs of deterioration after one month followed up.

Chest x-ray, before treatment, showed enlargement of cardiac silhouette, interstitial pulmonary infiltrations notably in the left hillus of the lungs (Figure 1); chest x-ray one month after treatment showed improvement compared to previous x-ray (the heart reached normal size), but pulmonary instertitial infiltrate is evidenced in left lobe hiliar (Figure 2).

Mantoux tuberculin skin test, 22 mm in diameter, indicating size of induration is positive (Figure 3); Echocardiology showed pericardial effusion ± 200-300cc (Figure 4); six month echocardiography follow up shows no pericardial effusion (Figure 5).
Discussion

Echocardiography is an accurate and noninvasive method for the diagnosis of pericardial effusion. The chest radiograph shows an enlargement of cardiac shadow. In Indonesia and other developing countries in which TB is endemic, tuberculin skin test has a little value of diagnostic because of mass BCG immunization, but highly positive skin induration more than 10 mm has 89% sensitivity and 56% specificity. Direct methods for the diagnosis of a tuberculous pathogenesis must be established as far as possible by a diligent search for acid-fast bacilli in pericardial fluid. Pericardiocentesis is recommended in all patients in whom tuberculosis pericarditis is suspected. In this case due to limitation of tools and diagnostic approach we did not perform the pericardiocentesis, we applied tygerberg TB pericarditis diagnostic score to establish the diagnosis of tuberculous pericarditis. Tygerberg TB pericarditis diagnostic score is applicable when pericardiocentesis is not feasible and has 86% sensitivity and 85% specificity.

We applied tygerberg TB pericarditis diagnostic score resulted total score of 10, which was highly indicated for tuberculous pericarditis. Therefore, the diagnosis was made without serologic and or microbiology confirmation of pericardial fluid; the patient received antituberculous chemotherapy. Tuberculin skin test has a little value of diagnostic, but large diameter of skin induration more than 10 mm is highly suspicious for TB. In this patient we find large diameter of skin induration 22 mm, that highly suspicious for TB infection.

Without specific contraindication, corticosteroid should be prescribed in addition to antituberculosis chemotherapy to prevent constrictive pericarditis. Using Tygerberg TB pericarditis diagnostic tool and tuberculin skin test, we made a accurate diagnosis, which proved by good respond of the treatment. The patient was discharged from the hopsital in a good condition and one month followed up using chest x ray revealed no enlargement of cardiac silhouette and echocardiography showed normal heart without effusion.

Conclusion

Where the diagnostic tools and resources are available, suspected cases of tuberculous pericarditis may be diagnosed using isolation of *M. tuberculosis* from the drained pericardial effusion or pericardial biopsy, but it is often difficult in the resource with limited setting, where the paucity of evidence to support clinical decisions is emphasized and the need for well designed diagnostic and therapeutic studies is highlighted. In the absence of sufficient tools and diagnostic approach and pericardiocentesis is not feasible, it is appropriate in high prevalence areas to initiate empiric antituberculosis therapy in the presence of pericardial effusion and tygerberg TB pericarditis diagnostic score ≥ 6.
